

THE METHOD FOR THE MASS PROPAGATION OF ADVENTITIOUS ROOTS OF GINSENG, CAMPHOR GINSENG AND WILD GINSENG BY TISSUE CULTURE AND THE IMPROVEMENT OF THEIR SAPONIN CONTENT

Technical Field

The present invention relates to the method for mass propagation of adventitious roots of ginseng, camphor ginseng, and wild ginseng by tissue culture and the improvement of their saponin content. More specifically the present invention relates to a method for improvement of saponin content and mass propagation of adventitious roots of ginseng, camphor ginseng, and wild ginseng by tissue culture which can produce in vitro adventitious roots that have excellent commercial value and effectiveness. This product was produced by including adventitious roots from callus, which was formed by tissue culturing of the leaf, root and stem of cultivated ginseng, camphor ginseng, and wild ginseng. After inducing the adventitious roots, it was mass propagated by shaking incubation or bioreactor incubation. In the mass propagation process, the optimal cultivating conditions which the saponin contents in the cultivated ginseng or wild ginseng yields almost the same contents in the natural ginseng were identified.

Background Art

Botanically, ginsengs belong in Panax genus of Araliaceae family and their roots are used for medical purposes.

Globally, 6-7 plant species are known to belong to this species. Also, 3

types of the ginsengs are cultivated economically and traded in the ginseng market.

Geographically, ginseng whose plant name is "Panax ginseng C.A. Meyer" is distributed and cultivated at Far East Asia and was used for a tonic medicine, which is traditionally the most important oriental herb medicine in china.

Ginseng has been known to have excellent effects in curing and promoting recovery from diverse diseases and a broad research on ginseng's drug action component and pharmacological effect have been conducted.

Until now, the scientifically proved important major effect is the maintenance of homeostasis of body control function. Based on this function, anti-fatigue and anti-stress effect, anti-diabetes effect, blood pressure control effect, anti-cancer effect, prevention of arteriosclerosis and high blood pressure, brain function fortification, gastrointestinal function reinforcement, immunity reinforcement, anti-virus effect are to be reported.

The primary effective components of ginseng are saponin, sapogenin, polyacetylene, pyrogen derivatives, maltol.

However, it has some uneconomical aspects due to the facts that the natural ginseng, which has medical purposes, requires a long-term cultivation at the well drainage and cool highlands for 4-6 years. Also, it will be affected by the natural climate and will not be able to crop continuously, thus appearing uneconomically.

Accordingly, the plant tissue cultivating research has been studied to produce mass propagation of the precious medical ginseng all year around without any impaction of the climate. The method is to produce a ginseng tissue that has as much effective component as the natural medical ginseng by

cultivating an indeterminate form of callus, which is obtained by culturing the root of the natural medical ginseng, in various nutrient media under different environmental conditions.

The technology of the mass propagating method of ginseng trichoid root (hairy root) has been registered as a domestic patent under the public patent number of 1993-0000004.

At present, the technology for tissue culturing of Korean ginseng, American ginseng and Tenchi ginseng for multipurpose is commonly practiced. In particular, the cultivation of callus, which was obtained from culturing various tissues of ginseng, organ differentiation and the successful cell culture of callus, are reported in the professional journals. However these experiments are mainly confined in the analysis of the impacts of the physical and chemical factors on the propagation of callus and cell. But not so many experiments have been reported on the cultivation of adventitious roots of ginseng. The utilization of ginseng requires a lot of effort including a long growing time of 5-6 years or at least 3-4 years and the difficulty of rotating crops. Nevertheless the demand of ginseng is ever growing for the usage in foods, cosmetics and medicine etc.

Disclosure of Invention

The present invention was invented based on the above-mentioned facts. The object of the present invention is to examine closely to the factors that affect the mass propagation of adventitious roots of ginseng, camphor ginseng, and wild ginseng so as to produce the ginseng all year around in the growth controller through the tissue culture of adventitious roots of ginseng, camphor ginseng, and wild ginseng in a shaking incubator or in a bioreactor. In the mean time the

present invention is to provide an improved method for increasing saponin content in the adventitious roots of ginseng, camphor ginseng, and wild ginseng compared with the cultivated ginseng and wild ginseng and to induce the level of the saponin composition ratio as same as the natural ginseng by finding the optimal cultivation condition. Therefore, the present invention makes it possible to produce high saponin contented ginseng that has high commercial value and effectiveness.

The other object of the present invention is to apply the present method of mass propagation of the adventitious roots to the high added value products including camphor ginseng, and wild ginseng so as to make it possible to provide and produce raw materials of foods and substitute medicines.

Best mode for carrying out the invention

To achieve the above objects of the present invention, the method for mass propagating the adventitious roots of ginseng, camphor ginseng, and wild ginseng comprises the steps of:

Culturing the tissues of root, stem, leaf from ginseng, camphor ginseng, cultivated ginseng and wild ginseng and desertion callus;

Propagating the developed adventitious root that was deserted from callus;
and

Mass culturing the propagated adventitious root in the bioreactor.

The method to improve the saponin content of tissue cultured adventitious root for the mass propagation comprises the steps of:

Preprocessing of the one of adventitious root, obtained from tissue culturing of the ginseng, camphor ginseng, and wild ginseng using a growth

regulator;

Seeding the preprocessed adventitious root in the media containing jasmonic acid or methyl jasmonic acid;

Culturing the adventitious root under the light in a balloon shaped or conical shaped bioreactor; and

Transferring the adventitious root to nitrogen excluded media within 5-10days before harvest.

The method for the improvement of saponin content of the tissue cultured adventitious root for the mass propagation is to increase the diol-saponin and the triol-saponin of the adventitious root to the level of those in natural ginseng, thereby providing adventitious roots that have enough commercial value and usefulness in their effects.

Therefore, the present invention makes it possible to produce organic ginseng that are not affected by environments, soils and various contamination by agricultural chemicals all year around in the laboratory or in the factory. Subsequently, this invention makes it possible to satisfy the consumer's desire for consumption by mass propagating the highly recognized wild ginseng in the standardized cultivator.

The primary object of the present invention was to examine closely the factors that affect the propagation of the adventitious root. The secondary object is to cultivate the adventitious root in a bioreactor using the most effective media and to examine the affect of the type of the bioreactor and the amount of the air injection to the bioreactor on the growth rate so as to solve the technical problems associated with the industrialization.

Therefore, the best mode for carrying out the invention consists following contents.

A 2-3mm² sized section was obtained from one of the sterilized ginseng, camphor ginseng, and wild ginseng and was seeded on a MS media containing 1.0-10.0mg/L of 2,4-D (2,4-dichlorophenoxy acetic acid), pochloram, NAA(naphthalemeacetic acid) to induce callus. The most desirable effect could be obtained when the concentration of added chemicals was 2.0mg/L.

After propagating the induced callus in a MS media containing 0.1-5.0mg/L of 2.4-D as a growth regulator, it was subcultured every 2-4 weeks. Then, transferred to a MS media containing 1.0-5.0mg/L of IBA or NAA to produce a adventitious root. Instead of using MS media, SH(Schenk and Hildebrandt) media, B5(Gamborg)media, LP(Quorin and Iepoivre)media and White media were used to propagate callus. But the similar effect was obtained except for the difference depending on the culturing period. Among them MS media and 3/4 SH media had the most desirable results. Also, a desirable result could be obtained when 1.0-5.0mg/L of NAA of IBA was used as a growth regulator that affects callus growth.

The above adventitious root was propagated in MS media (inorganic matter concentration 1/2-3/4, pH5.7-6.0, sugar concentration 3-5%) at the temperature of 18-24°C. The randomly sectioned newly formed lateral root including cultured explantss in a size of 1-2cm was seeded in a buoyant balloon type bioreactor and was cultured in a MS media containing 3% of sugar under the condition of 0.05-0.3vvm of air injection at 22°C and pH6.0 with a growth regulator of the 1.0-10.0mg/L BSSA(benzo [b] selenienyl acetic acid) or IBA or NAA.

It is desirable to increase the air injection amount in every 2 weeks to prevent the root tangling and to re-seed the adventitious root after 2weeks of incubation in a bioreactor to prevent rate decrease. It could be possible step by

step to mass propagate by scaling up to a 20-50ton of cultivating adventitious roots using a bigger bioreactor.

Examples

In this present invention, 6-year-old ginseng, 15-year-old camphor ginseng and over 100-year-old wild ginseng that were cultivated in a field were used for the following experiments.

Example 1: Experiment to set the optimum condition for adventitious root propagation.

After forming an adventitious root from callus, the following experiments have been conducted to examine the most effective optimum conditions to allow the maximum propagation in a shortest time and to minimize the production cost. After transferring 30ml of MS media containing 2.0mg/L of IBA to a disposable petri-dish, 30 adventitious roots sectioned by 10mm length on the average, which was originated from the wild ginseng callus was seeded.

The propagation speed of the adventitious root was examined under the various experimental conditions of the concentration of the inorganic matter in the media varying 1, 1/2 and 3/4 folds, the pH of the media varying 4.0, 5.0, 5.5, 5.7, 6.0, 6.5, the sugar concentration in the media varying 0%, 1%, 2%, 3%, 4%, 5%, 6%, 7% and the incubation temperature varying 15°C, 18°C, 20°C, 22°C, 24°C, and 26°C.

As a result, the optimum condition for the propagation of the adventitious root was found to be:

The concentration of the inorganic matter 1/2-3/4, pH 5.7-6.0,
sugar concentration 3-5% and the incubation temperature 18-24°C.

Example 2: The effect of the added growth regulator on the adventitious root propagation.

After adding 3% of sugar to the MS media and adjusting pH6.0, basal medium were made by adding 1mg/L, 2 mg/L, 3 mg/L, 5 mg/L of each of the IBA, NAA and BSAA as auxin. These basal mediums were divided into a 1L flask and a 5L bioreactor.

The roots (average length of 1.0cm) of the wild ginseng and the cultivated ginseng were seeded in the basal media. The growth increment was observed after 4weeks and the results are given in Table 1.

Table 1. Effects of the growth regulator on the propagation of the adventitious root.

Growth regulator (mg/L)		Cultivated ginseng (Increment rate of biomass)	Wild ginseng (Increment rate of biomass)
IBA	Control	1.7	1.5
	1	4.5	4.3
	2	6.7	6.8
	3	6.5	5.7
	5	3.8	4.2
NAA	1	3.2	3.4
	2	7.2	6.8
	3	6.7	6.2
	5	4.2	3.8
BSAA	1	5.3	5.0
	2	13.2	12.5
	3	11.4	11.7
	5	4.8	3.9

As indicated in table 1, media that had not treated by the growth regulator

showed less than 2 times of the biomass increment whereas the media treated by IBA, NAA showed more than 5 times of the biomass increment with the concentration of 2-3 mg/L. Especially, the media treated by BSSA, a newly synthesized auxin, showed a remarkable increment of the biomass under the concentration of 2-3 mg/L, suggesting the most effective concentration of the growth regulator of 2-3mg/L.

The comparison of the cultivated ginseng and the wild ginseng showed not so much difference in the biomass increment and a similar growth pattern in the bioreactor. Therefore, it is desirable to add growth regulators including NAA, IBA and BSSA to mass propagate the adventitious root of the ginseng in the bioreactor.

Example 3: The effect of seeding method on the adventitious root propagation.

To examine the effects of preparation methods on the root propagation when culturing the adventitious root of the cultivated ginseng and the wild ginseng in the bioreactor, the following method were used. The first one is to culture the non-sectioned adventitious root in a MS media containing 2ml/L of BSSA. The second one is to culture the lateral root only excluding the explantss and the last one is to culture the sectioned adventitious root of 1-2cm length including the explantss and lateral roots. Table 2 shows the results of each method after 4weeks cultivation.

Table 2. The effects of subculturing of the adventitious root on the biomass increase(After 4weeks culture).

Culturing method	Cultured ginseng		Wild ginseng	
	Biomass increment	Drymass increment	Biomass increment	Drymass increment
Culturing non-sectioned adventitious root	1.4	-	1.5	-
Culturing the lateral root only	11.2	13.6	10.5	10.8
Culturing the sectioned adventitious root of 1-2cm length including the explants and lateral roots	12.4	14.7	13.2	15.9

As shown in table 2, for the case of transplanting the lateral root with the explants to a new media, the lateral root has not been developed and the browning phenomenon has appeared so that the biomass had not been increased. On the other hand, for the case of culturing the sectioned lateral root instead of the originated explants, the biomass and the number of the developed lateral roots were increased. However, it took a long time to seed that it seemed to be not effective. For the case of seeding the newly developed lateral roots that were sectioned randomly in a length of 1-2cm, including the cultured explants, the rate of multiplication has been increased more than 15 times, indicating that this case was the most effective method for the increase of biomass weight. Therefore, It is desirable to seed the adventitious root having both the explants and the lateral root, which is sectioned in the length of 1-2cm.

Example 4: The effect of the bioreactor shape on the adventitious root propagation.

For the case of culturing the adventitious root using the bioreactor for the

mass propagation, the effect of the shape of bioreactor on the adventitious root propagation is examined for the following bioreactor shapes. The culturing has been done in a pilot scale of 500L, 1000L of a buoyant balloon shaped bioreactor and the 500L, 1000L of buoyant drum shaped bioreactor for 40 days. The effects of the shape of bioreactor on the biomass increment were compared and the results were given in table 3.

The temperature was adjust to 22°C, and the amount of air injection to the bioreactor was 0.05-0.3vvm. 3% sugar added MS media was used and 2.0mg/L of BSSA was added as a growth regulator and pH was adjusted to 6.0.

Table 3. The effect of the shape of bioreactor on the propagation of adventitious root of the wild ginseng (After 40 days culture).

The shape of incubator	Scale (L)	Primary seeding amount (kg)	Biomass (kg)	Drymass (kg)
Buoyant balloon shape	500	2	88	6.5
	1000	3	185	12.4
Buoyant drum shape	500	2	80	5.7
	1000	3	174	10.8

As shown in table 3, generally the buoyant balloon shaped bioreactor was more effective in increasing the biomass and drymass than the drum shaped bioreactor. It is desirable to prevent the root tangle by increasing air injection amount every 2 weeks because the adventitious root tangle occurs as the culturing time becomes longer. It is also desirable to prevent the total production amount decrease, caused by floating phenomenon of the adventitious root after 4

weeks of culturing. Therefore, it is also desirable to re-seed (1kg) after 2 weeks culturing. It is also desirable to use a 1-3 ton scaled up incubator with a knife in the attached motor so as to cut the newly developed adventitious root in a length of 2-3cm as in example 3 before using a 50L, 100L scale of a seed incubator or 20-50 ton scale of a incubator.

As shown in earlier, the method for the mass propagation of adventitious root of the ginseng, camphor ginseng and wild ginseng has been proven high productivity of biomass, convenient to handle and have a tendency to increase the drymass. Therefore, it is an innovative method for mass production. Also the present invention made it possible to propagate the adventitious root of cultivated ginseng, camphor ginseng and wild ginseng by tissue culture using the adventitious root propagation method in the MS media, SH media and B5 media. The present invention provides not only the method to increase the saponin content of the harvested adventitious root or the adventitious root under culturing process but also the way to regulate the trio/diol ratio close to the natural ginseng level.

Example 5. The effect of the bioreactor shape on the saponin content.

After seeding the adventitious root, which was sectioned in a length of 1-2cm in a MS media or SH media containing 3% of sugar, 2.0mg/L of IBA, the flask and a balloon shape, conical shape, bulb shape and drum shape incubator were used to culture the adventitious root. After 4 weeks, the saponin content was increased. The results are given in table 4.

The measurement of saponin content was followed by the standard method for the analysis of ginseng constituent of The Korean Ginseng Research Institute.

Table 4. Comparison of saponin content by shape of the culture instrument.

Shape of culture instrument	Ginsenoside content (mg. 1g drymass)			Ginsenoside productivity (mg.L)
	Rg group	Rb group	total content	
Balloon shape	4.62	7.72	12.34	124.63
Conical shape	4.50	7.74	12.14	110.47
Bulb shape	3.67	5.96	9.63	61.63
Drum shape	3.33	4.68	8.01	28.84
△ -flask	2.87	4.92	7.79	33.50

As shown in table 4, the saponin content was high when cultured in the conical shape bioreactor or the balloon shape bioreactor, but when cultured in the drum shaped or flask the saponins content was low. Therefore, it was desirable to use a balloon shape or conical shape bioreactor when culturing the adventitious root of the ginseng, camphor ginseng and wild ginseng.

Example 6. The effect of jasmonic acid and methyl jasmonic acid treatment on the saponin content.

While culturing the adventitious root of cultivate ginseng, camphor ginseng, wild ginseng in a balloon shape bioreactor, the saponin content in the adventitious root was examined at the initial time, 10 days before harvest, and after harvest with the treatment of various concentrations of jasmonic acid and methyl jasmonic acid.

The experiment was conducted under the conditions of pH 6.0 and the MS media added with 3% sugar and 2.0mg/L IBA.

The saponin content in the adventitious root was measured for the root treated by various concentrations of jamonic acid or methyl jamonic acid of 0, 1, 2, 5, 10 mg/L 10days before harvest and the root washed by tap water obtained

from the MS media not containing sugar or the treated root by tap water which includes jasmonic acid or methyl jasmonic acid, for one week. The result was given in table 5.

Table 5. The effect of jasmonic acid concentration.

Jasmonic acid Concentration (mg/L)	Ginsenoside content (mg. 1g drymass)			Rb/Rg
	Rg Group	Rb Group	Total content	
0	3.92	7.49	11.42	1.95
1	2.83	13.29	16.09	4.68
2	4.46	24.19	28.69	5.45
5	4.15	34.69	38.82	8.43
10	5.53	54.29	59.87	9.83

As shown in table 5, In the initial culture treated by two materials, the growth increment was inhibited.

The saponin content reached 7-8% for the root treated by the bioreactor for 10 days before harvest or after 7days for the propagated adventitious root after harvest that was washed by water and then treated by jasmonic acid or methyl jasmonic acid.

This suggests that the saponin content was remarkably increased compared to that of the cultivated ginseng whose saponin content was 2-3%. However, the ratio of the diol and triol tended to increase more for the treated ginseng than the cultivated ginseng.

Therefore, it is desirable to treat the root with jasmonic acid or methyl jasmonic acid since the jasmonic acid treated root has total saponin content more than 6 times higher than the non-treated one.

Example 7: The effect of the nitrogen elimination in the media on the saponin

content.

When culturing adventitious root of ginseng in a 5L conical shape bioreactor to increase the saponin content, the MS media containing 2.0mg/L of IBA and 3% of sugar with a fixed pH value of 6.0 was used.

After culturing 20-30 days to reach the maximum propagation of the adventitious root, the root was transferred to the media that was not contained nitrogen for 5-10 days before harvest and the saponin content of this root was examined. The results were given in table 6.

Table 6. The effect of the media not treated by nitrogen before harvest on the saponin content.

Treated root	Ginsenoside content (mg·1g drymass)			Remarks
	Rg group	Rb group	total	
Control	3.8	7.4	11.2	
Root not treated by nitrogen	4.6	9.8	15.4	

As shown in table 6, the saponin content was increased in adventitious root which was cultured in media with nitrogen by optimum concentration and then was transferred to a new media for 5-10 days before harvest.

When transferring the media, nitrogen in the form of nitrate and ammonium should not be added and at this time as shown in example 6, adding jasmonic acid could increase the saponin content more effectively.

Example 8. The effect of light sources on saponin content.

To know the effect of various light sources on the saponin content and the saponin ratio of diol and triol during the incubation period of the adventitious root of the cultivate ginseng, camphor ginseng, wild ginseng, 30ml of MS media,

that had the same condition described in example 1 was transferred to a 100mL flask and then ginseng adventitious roots, which were sectioned at the length of 1-2cm were seeded. Subsequently, they were cultured under the dark condition and red light(650nm), blue light(430nm), methyl halite and a fluorescent light intensity of 40 μ mol.m⁻².s⁻¹ for 16-24 hours. The cultivating room temperature was adjusted to 22-25 °C.

The saponin content was measured after 4 weeks later. The results are given in table 7.

Table 7. The effects of light intensity and light source on the saponin content.

Light source	Biomass increment	Saponin content(mg.g ⁻¹ DW)			Saponin productivity
		Rg group	Rb group	total	
Dark	11.41	2.8	4.5	1.61	
fluorescent light	10.09	5.3	3.7	0.70	
methyl halite	8.87	3.5	3.4	0.97	
blue light	11.26	3.8	3.9	1.03	
red light	11.64	3.1	4.1	1.32	
blue light+red light	10.09	3.4	2.9	0.85	

As shown in table 7, it was desirable to culture under the fluorescence light than the dark condition. It was turned out that the treatment with cytokinins or jasmonic acid was highly effective to improve the quality of the adventitious root before incubating.

As mentioned above, the biomass increment of ginseng, camphor ginseng and wild ginseng by tissue culture was decreased but the saponin content, especially the triol saponin has increased.

Also, when culturing under blue light, the ratio of diol and triol was 1:1, which was close to the ratio of the natural ginseng of 1.03. The red light also

showed a similar result.

Therefore, increasing the triol saponin content among total saponin contents, which was one of the difficult problems in culturing the adventitious root of ginseng, had been solved effectively. It was an important factor to culture the adventitious root of ginseng under fluorescence light, red light and blue light to maintain the saponin content close to the level of natural ginseng.

Example 9: The effect of the growth regulator treatment on the saponin content and saponin ratio.

Among growth regulators, BA(benzyl adenine) 2iP, zeatin, methyl jasmonic acid, TDZ, kinetin, which are included in cytokinin groups was treated 1-10 hours before culturing the root tissue of cultivated ginseng, camphor ginseng, and wild ginseng at the concentration of 1-100 mg/L. Immediate after the pretreatment the saponin and the diol:triol content were compared and analyzed. The results were given in Table 8.

Table 8. The effect of the growth regulator treatment before culturing on the saponin components.

Treatment	saponin content	triol/diol	remarks
No treatment	1.56	2.02	
BA treatment	1.23	1.63	
Methyl jasmonate or jasmonic acid	6.50	2.40	TDZ, kinetin, 2iP and zeatin show similar results

As shown in table 8, culturing the adventitious root after pre-treatment increased the saponin content by 5 times and the ratio of triol to diol was about

2.4 that was almost the same value in the natural ginseng. In particular, the treatment with the cytokinin groups gave rise to decrease in the saponin content but the ratio of triol and diol was quite similar to that of the naturally cultivated ginseng. Therefore the method to improve the saponin content as maintaining the triol: diol ratio of the cultured adventitious root to 1:1-1:2 was to examine closely the optimum conditions considering the shape of bioreactor, various kinds of growth regulators and their optimum treatment period, media with or without nitrogen treatment and light sources. The present method was an excellent method being able to culture the adventitious root that had the saponin content exceeding the natural ginseng and the ratio of saponin composition being similar to that of the natural ginseng.

Industrial applicability

As indicated through the examples, the present invention is to establish the optimum propagation condition including the proper media, pH of the media, sugar concentration, proper culturing temperature, kinds of growth regulators for culturing the adventitious roots of ginseng, camphor ginseng, and wild ginseng in a bioreactor, and to industrialize the production of the adventitious roots in the bioreactor through the simplified method of the adventitious root seeding and finding a proper shape of bioreactor that could boost the productivity and propagation which was not invented yet. The present invention was able to produce high additive value of ginseng, camphor ginseng, and wild ginseng all year around without influence of the climate and environmental conditions, and to produce in vitro adventitious root that has 2-3 times higher saponin content compared with the natural ginseng and the similar ratio of diol and triol saponin

to that of the natural ginseng by taking optimum conditions including the nitrogen supply interruption to the adventitious root after maximum growth and the light treatment etc.
